Although integers provide an exact representation for numeric values, they suffer from two major drawbacks: the inability to represent fractional values and a limited dynamic range. Floating point arithmetic solves these two problems at the expense of accuracy and, on some processors, speed. Most programmers are aware of the speed loss associated with floating point arithmetic; however, they are blithely unaware of the problems with accuracy.

For many applications, the benefits of floating point outweigh the disadvantages. However, to properly use floating point arithmetic in any program, you must learn how floating point arithmetic operates. Intel, understanding the importance of floating point arithmetic in modern programs, provided support for floating point arithmetic in the earliest designs of the 8086 – the 80x87 FPU (floating point unit or math coprocessor). However, on processors earlier than the 80486 (or on the 80486sx), the floating point processor is an optional device; it this device is not present you must simulate it in software.

This chapter contains four main sections. The first section discusses floating point arithmetic from a mathematical point of view. The second section discusses the binary floating point formats commonly used on Intel processors. The third discusses software floating point and the math routines from the UCR Standard Library. The fourth section discusses the 80x87 FPU chips.

### 14.0 Chapter Overview

This chapter contains four major sections: a description of floating point formats and operations (two sections), a discussion of the floating point support in the UCR Standard Library, and a discussion of the 80x87 FPU (floating point unit). The sections below that have a “•” prefix are essential. Those sections with a “•” discuss advanced topics that you may want to put off for a while.

- The mathematics of floating point arithmetic.
- IEEE floating point formats.
- The UCR Standard Library floating point routines.
- The 80x87 floating point coprocessors.
- FPU data movement instructions.
  - Conversions.
  - Arithmetic instructions.
  - Comparison instructions.
  - Constant instructions.
  - Transcendental instructions.
  - Miscellaneous instructions.
  - Integer operations.
  - Additional trigonometric functions.

### 14.1 The Mathematics of Floating Point Arithmetic

A big problem with floating point arithmetic is that it does not follow the standard rules of algebra. Nevertheless, many programmers apply normal algebraic rules when using floating point arithmetic. This is a source of bugs in many programs. One of the primary goals of this section is to describe the limitations of floating point arithmetic so you will understand how to use it properly.

Normal algebraic rules apply only to infinite precision arithmetic. Consider the simple statement $x := x + 1$, $x$ is an integer. On any modern computer this statement follows the normal rules of algebra as long as overflow does not occur. That is, this statement is valid only for
certain values of \( x \) \((\text{minint} \leq x < \text{maxint})\). Most programmers do not have a problem with this because they are well aware of the fact that integers in a program do not follow the standard algebraic rules (e.g., \( 5/2 \neq 2.5 \)).

Integers do not follow the standard rules of algebra because the computer represents them with a finite number of bits. You cannot represent any of the (integer) values above the maximum integer or below the minimum integer. Floating point values suffer from this same problem, only worse. After all, the integers are a subset of the real numbers. Therefore, the floating point values must represent the same infinite set of integers. However, there are an infinite number of values between any two real values, so this problem is infinitely worse. Therefore, as well as having to limit your values between a maximum and minimum range, you cannot represent all the values between those two ranges, either.

To represent real numbers, most floating point formats employ scientific notation and use some number of bits to represent a mantissa and a smaller number of bits to represent an exponent. The end result is that floating point numbers can only represent numbers with a specific number of significant digits. This has a big impact on how floating point arithmetic operations. To easily see the impact of limited precision arithmetic, we will adopt a simplified decimal floating point format for our examples. Our floating point format will provide a mantissa with three significant digits and a decimal exponent with two digits. The mantissa and exponents are both signed values (see Figure 14.1).

When adding and subtracting two numbers in scientific notation, you must adjust the two values so that their exponents are the same. For example, when adding \( 1.23\times10^3 \) and \( 4.56\times10^0 \), you must adjust the values so they have the same exponent. One way to do this is to convert \( 4.56\times10^0 \) to \( 0.456\times10^1 \) and then add. This produces \( 1.686\times10^1 \). Unfortunately, the result does not fit into three significant digits, so we must either round or truncate the result to three significant digits. Rounding generally produces the most accurate result, so let’s round the result to obtain \( 1.69\times10^1 \). As you can see, the lack of precision (the number of digits or bits we maintain in a computation) affects the accuracy (the correctness of the computation).

In the previous example, we were able to round the result because we maintained four significant digits during the calculation. If our floating point calculation is limited to three significant digits during computation, we would have had to truncate the last digit of the smaller number, obtaining \( 1.68\times10^1 \) which is even less correct. Extra digits available during a computation are known as guard digits (or guard bits in the case of a binary format). They greatly enhance accuracy during a long chain of computations.

The accuracy loss during a single computation usually isn’t enough to worry about unless you are greatly concerned about the accuracy of your computations. However, if you compute a value which is the result of a sequence of floating point operations, the error can accumulate and greatly affect the computation itself. For example, suppose we were to add \( 1.23\times10^3 \) with \( 1.00\times10^0 \). Adjusting the numbers so their exponents are the same before the addition produces \( 1.23\times10^3 + 0.001\times10^3 \). The sum of these two values, even after rounding, is \( 1.23\times10^3 \). This might seem perfectly reasonable to you; after all, we can only maintain three significant digits, adding in a small value shouldn’t affect the result at all. However, suppose we were to add \( 1.00\times10^0 \times 1.23\times10^3 \) ten times. The first time we add \( 1.00\times10^0 \) to \( 1.23\times10^3 \) we get \( 1.23\times10^3 \). Likewise, we get this same result the second, third, fourth, ..., and tenth time we add \( 1.00\times10^0 \) to \( 1.23\times10^3 \). On the other hand, had we added \( 1.00\times10^0 \) to itself ten times, then added the result \((1.00\times10^1)\) to \( 1.23\times10^3 \), we would have gotten a different result, \( 1.24\times10^3 \). This is the most important thing to know about limited precision arithmetic:
The order of evaluation can effect the accuracy of the result.

You will get more accurate results if the relative magnitudes (that is, the exponents) are close to one another. If you are performing a chain calculation involving addition and subtraction, you should attempt to group the values appropriately.

Another problem with addition and subtraction is that you can wind up with false precision. Consider the computation 1.23e0 - 1.22 e0. This produces 0.01e0. Although this is mathematically equivalent to 1.00e-2, this latter form suggests that the last two digits are exactly zero. Unfortunately, we've only got a single significant digit at this time. Indeed, some FPUs or floating point software packages might actually insert random digits (or bits) into the L.O. positions. This brings up a second important rule concerning limited precision arithmetic:

*Whenever subtracting two numbers with the same signs or adding two numbers with different signs, the accuracy of the result may be less than the precision available in the floating point format.*

Multiplication and division do not suffer from the same problems as addition and subtraction since you do not have to adjust the exponents before the operation; all you need to do is add the exponents and multiply the mantissas (or subtract the exponents and divide the mantissas). By themselves, multiplication and division do not produce particularly poor results. However, they tend to multiply any error which already exists in a value. For example, if you multiply 1.23e0 by two, when you should be multiplying 1.24e0 by two, the result is even less accurate. This brings up a third important rule when working with limited precision arithmetic:

*Whenever subtracting two numbers with the same signs or adding two numbers with different signs, the accuracy of the result may be less than the precision available in the floating point format.*

Often, by applying normal algebraic transformations, you can arrange a calculation so the multiply and divide operations occur first. For example, suppose you want to compute \( x^*(y+z) \). Normally you would add \( y \) and \( z \) together and multiply their sum by \( x \). However, you will get a little more accuracy if you transform \( x^*(y+z) \) to get \( x^*y+x^*z \) and compute the result by performing the multiplications first.

Multiplication and division are not without their own problems. When multiplying two very large or very small numbers, it is quite possible for overflow or underflow to occur. The same situation occurs when dividing a small number by a large number or dividing a large number by a small number. This brings up a fourth rule you should attempt to follow when multiplying or dividing values:

*When multiplying and dividing sets of numbers, try to arrange the multiplications so that they multiply large and small numbers together; likewise, try to divide numbers that have the same relative magnitudes.*

Comparing floating pointer numbers is very dangerous. Given the inaccuracies present in any computation (including converting an input string to a floating point value), you should never compare two floating point values to see if they are equal. In a binary floating point format, different computations which produce the same (mathematical) result may differ in their least significant bits. For example, adding 1.31e0+1.69e0 should produce 3.00e0. Likewise, adding 2.50e0+1.50e0 should produce 3.00e0. However, were you to compare (1.31e0+1.69e0) against (2.50e0+1.50e0) you might find out that these sums are not equal to one another. The test for equality succeeds if and only if all bits (or digits) in the two operands are exactly the same. Since this is not necessarily true after two different floating point computations which should produce the same result, a straight test for equality may not work.

The standard way to test for equality between floating point numbers is to determine how much error (or tolerance) you will allow in a comparison and check to see if one value is within this error range of the other. The straight-forward way to do this is to use a test like the following:

```plaintext
if Value1 >= (Value2-error) and Value1 <= (Value2+error) then ...
```
Another common way to handle this same comparison is to use a statement of the form:

\[
\text{if abs(Value1-Value2) }\leq \text{error then ...}
\]

Most texts, when discussing floating point comparisons, stop immediately after discussing the problem with floating point equality, assuming that other forms of comparison are perfectly okay with floating point numbers. This isn’t true! If we are assuming that \( x = y \) if \( x \) is within \( y \pm \text{error} \), then a simple bitwise comparison of \( x \) and \( y \) will claim that \( x < y \) if \( y \) is greater than \( x \) but less than \( y + \text{error} \). However, in such a case \( x \) should really be treated as equal to \( y \), not less than \( y \). Therefore, we must always compare two floating point numbers using ranges, regardless of the actual comparison we want to perform. Trying to compare two floating point numbers directly can lead to an error. To compare two floating point numbers, \( x \) and \( y \), against one another, you should use one of the following forms:

\[
\begin{align*}
= & \quad \text{if abs}(x-y) \leq \text{error then ...} \\
\ne & \quad \text{if abs}(x-y) > \text{error then ...} \\
< & \quad \text{if } (x-y) < \text{error then ...} \\
\leq & \quad \text{if } (x-y) \leq \text{error then ...} \\
> & \quad \text{if } (x-y) > \text{error then ...} \\
\geq & \quad \text{if } (x-y) \geq \text{error then ...}
\end{align*}
\]

You must exercise care when choosing the value for \( \text{error} \). This should be a value slightly greater than the largest amount of error which will creep into your computations. The exact value will depend upon the particular floating point format you use, but more on that a little later. The final rule we will state in this section is

When comparing two floating point numbers, always compare one value to see if it is in the range given by the second value plus or minus some small error value.

There are many other little problems that can occur when using floating point values. This text can only point out some of the major problems and make you aware of the fact that you cannot treat floating point arithmetic like real arithmetic – the inaccuracies present in limited precision arithmetic can get you into trouble if you are not careful. A good text on numerical analysis or even scientific computing can help fill in the details which are beyond the scope of this text. If you are going to be working with floating point arithmetic, in any language, you should take the time to study the effects of limited precision arithmetic on your computations.

### 14.2 IEEE Floating Point Formats

When Intel planned to introduce a floating point coprocessor for their new 8086 microprocessor, they were smart enough to realize that the electrical engineers and solid-state physicists who design chips were, perhaps, not the best people to do the necessary numerical analysis to pick the best possible binary representation for a floating point format. So Intel went out and hired the best numerical analyst they could find to design a floating point format for their 8087 FPU. That person then hired two other experts in the field and the three of them (Kahn, Coonan, and Stone) designed Intel’s floating point format. They did such a good job designing the KCS Floating Point Standard that the IEEE organization adopted this format for the IEEE floating point format.\(^1\)

To handle a wide range of performance and accuracy requirements, Intel actually introduced three floating point formats: single precision, double precision, and extended precision. The single and double precision formats corresponded to C’s float and double types or FORTRAN’s real and double precision types. Intel intended to use extended precision for long chains of computations. Extended precision contains 16 extra bits that the

---

1. There were some minor changes to the way certain degenerate operations were handled, but the bit representation remained essentially unchanged.
calculations could use for guard bits before rounding down to a double precision value when storing the result.

The single precision format uses a one’s complement 24 bit mantissa and an eight bit excess-128 exponent. The mantissa usually represents a value between 1.0 to just under 2.0. The H.O. bit of the mantissa is always assumed to be one and represents a value just to the left of the binary point. The remaining 23 mantissa bits appear to the right of the binary point. Therefore, the mantissa represents the value:

$$1.mmm...$$

The “$mmm...$” characters represent the 23 bits of the mantissa. Keep in mind that we are working with binary numbers here. Therefore, each position to the right of the binary point represents a value (zero or one) times a successive negative power of two. The implied one bit is always multiplied by $2^0$, which is one. This is why the mantissa is always greater than or equal to one. Even if the other mantissa bits are all zero, the implied one bit always gives us the value one. Of course, even if we had an almost infinite number of one bits after the binary point, they still would not add up to two. This is why the mantissa can represent values in the range one to just under two.

Although there are an infinite number of values between one and two, we can only represent eight million of them because we a 23 bit mantissa (the 24th bit is always one). This is the reason for inaccuracy in floating point arithmetic – we are limited to 23 bits of precision in computations involving single precision floating point values.

The mantissa uses a one’s complement format rather than two’s complement. This means that the 24 bit value of the mantissa is simply an unsigned binary number and the sign bit determines whether that value is positive or negative. One’s complement numbers have the unusual property that there are two representations for zero (with the sign bit set or clear). Generally, this is important only to the person designing the floating point software or hardware system. We will assume that the value zero always has the sign bit clear.

To represent values outside the range 1.0 to just under 2.0, the exponent portion of the floating point format comes into play. The floating point format raise two to the power specified by the exponent and then multiplies the mantissa by this value. The exponent is eight bits and is stored in an excess-127 format. In excess-127 format, the exponent $2^0$ is represented by the value 127 (7fh). Therefore, to convert an exponent to excess-127 format simply add 127 to the exponent value. The use of excess-127 format makes it easier to compare floating point values. The single precision floating point format takes the form shown in Figure 14.2.

With a 24 bit mantissa, you will get approximately 6½ digits of precision (one half digit of precision means that the first six digits can all be in the range 0..9 but the seventh digit can only be in the range 0..x where x<9 and is generally close to five). With an eight

---

2. The binary point is the same thing as the decimal point except it appears in binary numbers rather than decimal numbers.
3. Actually, this isn’t necessarily true. Thye IEEE floating point format supports denormalized values where the H.O. bit is not zero. However, we will ignore denormalized values in our discussion.
Chapter 14

The bit excess-128 exponent, the dynamic range of single precision floating point numbers is approximately $2^{128}$ or about $10^{38}$.

Although single precision floating point numbers are perfectly suitable for many applications, the dynamic range is somewhat small for many scientific applications and the very limited precision is unsuitable for many financial, scientific, and other applications. Furthermore, in long chains of computations, the limited precision of the single precision format may introduce serious error.

The double precision format helps overcome the problems of single precision floating point. Using twice the space, the double precision format has an 11-bit excess-1023 exponent and a 53 bit mantissa (with an implied H.O. bit of one) plus a sign bit. This provides a dynamic range of about $10^{308}$ and 14-1/2 digits of precision, sufficient for most applications. Double precision floating point values take the form shown in Figure 14.3.

Double precision floating point values take the form shown in Figure 14.3.

In order to help ensure accuracy during long chains of computations involving double precision floating point numbers, Intel designed the extended precision format. The extended precision format uses 80 bits. Twelve of the additional 16 bits are appended to the mantissa, four of the additional bits are appended to the end of the exponent. Unlike the single and double precision values, the extended precision format does not have an implied H.O. bit which is always one. Therefore, the extended precision format provides a 64 bit mantissa, a 15 bit excess-16383 exponent, and a one bit sign. The format for the extended precision floating point value is shown in Figure 14.4.

On the 80x87 FPUs and the 80486 CPU, all computations are done using the extended precision form. Whenever you load a single or double precision value, the FPU automatically converts it to an extended precision value. Likewise, when you store a single or double precision value to memory, the FPU automatically rounds the value down to the appropriate size before storing it. By always working with the extended precision format, Intel guarantees a large number of guard bits are present to ensure the accuracy of your computations. Some texts erroneously claim that you should never use the extended precision format in your own programs, because Intel only guarantees accurate computations when using the single or double precision formats. This is foolish. By performing all computations using 80 bits, Intel helps ensure (but not guarantee) that you will get full 32 or 64 bit accuracy in your computations. Since the 80x87 FPUs and 80486 CPU do not provide a large number of guard bits in 80 bit computations, some error will inevitably creep into the L.O. bits of an extended precision computation. However, if your computation is correct to 64 bits, the 80 bit computation will always provide at least 64 accurate bits. Most of the time you will get even more. While you cannot assume that you get an accurate 80
bit computation, you can usually do better than 64 when using the extended precision format.

To maintain maximum precision during computation, most computations use normalized values. A normalized floating point value is one that has a H.O. mantissa bit equal to one. Almost any non-normalized value can be normalized by shifting the mantissa bits to the left and decrementing the exponent by one until a one appears in the H.O. bit of the mantissa. Remember, the exponent is a binary exponent. Each time you increment the exponent, you multiply the floating point value by two. Likewise, whenever you decrement the exponent, you divide the floating point value by two. By the same token, shifting the mantissa to the left one bit position multiplies the floating point value by two; likewise, shifting the mantissa to the right divides the floating point value by two. Therefore, shifting the mantissa to the left one position and decrementing the exponent does not change the value of the floating point number at all.

Keeping floating point numbers normalized is beneficial because it maintains the maximum number of bits of precision for a computation. If the H.O. bits of the mantissa are all zero, the mantissa has that many fewer bits of precision available for computation. Therefore, a floating point computation will be more accurate if it involves only normalized values.

There are two important cases where a floating point number cannot be normalized. The value 0.0 is a special case. Obviously it cannot be normalized because the floating point representation for zero has no one bits in the mantissa. This, however, is not a problem since we can exactly represent the value zero with only a single bit.

The second case is when we have some H.O. bits in the mantissa which are zero but the biased exponent is also zero (and we cannot decrement it to normalize the mantissa). Rather than disallow certain small values, whose H.O. mantissa bits and biased exponent are zero (the most negative exponent possible), the IEEE standard allows special denormalized values to represent these smaller values. Although the use of denormalized values allows IEEE floating point computations to produce better results than if underflow occurred, keep in mind that denormalized values offer less bits of precision and are inherently less accurate.

Since the 80x87 FPUs and 80486 CPU always convert single and double precision values to extended precision, extended precision arithmetic is actually faster than single or double precision. Therefore, the expected performance benefit of using the smaller formats is not present on these chips. However, when designing the Pentium/586 CPU, Intel redesigned the built-in floating point unit to better compete with RISC chips. Most RISC chips support a native 64 bit double precision format which is faster than Intel’s extended precision format. Therefore, Intel provided native 64 bit operations on the Pentium to better compete against the RISC chips. Therefore, the double precision format is the fastest on the Pentium and later chips.

14.3 The UCR Standard Library Floating Point Routines

In most assembly language texts, which bother to cover floating point arithmetic, this section would normally describe how to design your own floating point routines for addition, subtraction, multiplication, and division. This text will not do that for several reasons. First, to design a good floating point library requires a solid background in numerical analysis; a prerequisite this text does not assume of its readers. Second, the UCR Standard Library already provides a reasonable set of floating point routines in source code form; why waste space in this text when the sources are readily available elsewhere? Third, floating point units are quickly becoming standard equipment on all modern CPUs or motherboards; it makes no more sense to describe how to manually perform a floating point computation than it does to describe how to manually perform an integer computation. Therefore, this section will describe how to use the UCR Standard Library routines if

---

4. The alternative would be to underflow the values to zero.
you do not have an FPU available; a later section will describe the use of the floating point unit.

The UCR Standard Library provides a large number of routines to support floating point computation and I/O. This library uses the same memory format for 32, 64, and 80 bit floating point numbers as the 80x87 FPU. The UCR Standard Library’s floating point routines do not exactly follow the IEEE requirements with respect to error conditions and other degenerate cases, and it may produce slightly different results than an 80x87 FPU, but the results will be very close\(^5\). Since the UCR Standard Library uses the same memory format for 32, 64, and 80 bit numbers as the 80x87 FPU, you can freely mix computations involving floating point between the FPU and the Standard Library routines.

The UCR Standard Library provides numerous routines to manipulate floating point numbers. The following sections describe each of these routines, by category.

### 14.3.1 Load and Store Routines

Since 80x86 CPUs without an FPU do not provide any 80-bit registers, the UCR Standard Library must use memory-based variables to hold floating point values during computation. The UCR Standard Library routines use two pseudo registers, an accumulator register and an operand register, when performing floating point operations. For example, the floating point addition routine adds the value in the floating point operand register to the floating point accumulator register, leaving the result in the accumulator. The load and store routines allow you to load floating point values into the floating point accumulator and operand registers as well as store the value of the floating point accumulator back to memory. The routines in this category include \texttt{accop}, \texttt{xaccop}, \texttt{lsfpa}, \texttt{sdfpa}, \texttt{lfpa}, \texttt{sfpa}, \texttt{lfpal}, \texttt{lsfpo}, \texttt{ldfpo}, \texttt{lefpo}, and \texttt{lefpol}.

The \texttt{accop} routine copies the value in the floating point accumulator to the floating point operand register. This routine is useful when you want to use the result of one computation as the second operand of a second computation.

The \texttt{xaccop} routine exchanges the values in the floating point accumulator and operand registers. Note that many floating point computations destroy the value in the floating point operand register, so you cannot blindly assume that the routines preserve the operand register. Therefore, calling this routine only makes sense after performing some computation which you know does not affect the floating point operand register.

\texttt{lsfpa}, \texttt{ldfpa}, and \texttt{lefpa} load the floating point accumulator with a single, double, or extended precision floating point value, respectively. The UCR Standard Library uses its own internal format for computations. These routines convert the specified values to the internal format during the load. On entry to each of these routines, \texttt{es:di} must contain the address of the variable you want to load into the floating point accumulator. The following code demonstrates how to call these routines:

```
  rVar  real14  1.0
  drVar real18 2.0
  xrVar real10 3.0

  lesi  rVar
  lsfpa
  ...
  lesi  drVar
  ldfpa

  ...
```

---

5. Note, by the way, that different floating point chips, especially across different CPU lines, but even within the Intel family, produce slightly different results. So the fact that the UCR Standard Library does not produce the exact same results as a particular FPU is not that important.
The `lesi`, `lefpa`, and `letpa` routines are similar to the `lsfpa`, `ldfpa`, and `lefpa` routines except, of course, they load the floating point operand register rather than the floating point accumulator with the value at address `es:di`.

`lefpal` and `lefpol` load the floating point accumulator or operand register with a literal 80 bit floating point constant appearing in the code stream. To use these two routines, simply follow the call with a `real10` directive and the appropriate constant, e.g.,

```
lefpal
real10 1.0
lefpol
real10 2.0e5
```

The `ssfpa`, `sdfpa`, and `sefpa` routines store the value in the floating point accumulator into the memory based floating point variable whose address appears in `es:di`. There are no corresponding `ssfpo`, `sdfpo`, or `sefpo` routines because a result you would want to store should never appear in the floating point operand register. If you happen to get a value in the floating point operand that you want to store into memory, simply use the xaccop routine to swap the accumulator and operand registers, then use the store accumulator routines to save the result. The following code demonstrates the use of these routines:

```
rVar real4 1.0
drVar real8 2.0
xrVar real10 3.0
... 
lesi rVar
ssfpa
... 
lesi drVar
sdfpa
... 
lesi xrVar
sefpa
```

### 14.3.2 Integer/Floating Point Conversion

The UCR Standard Library includes several routines to convert between binary integers and floating point values. These routines are `itof`, `utof`, `ltof`, `ultof`, `ftoi`, `ftou`, `ftol`, and `ftoul`. The first four routines convert signed and unsigned integers to floating point format, the last four routines truncate floating point values and convert them to an integer value.

`itof` converts the signed 16-bit value in `ax` to a floating point value and leaves the result in the floating point accumulator. This routine does not affect the floating point operand register. `utof` converts the unsigned integer in `ax` in a similar fashion. `ltof` and `ultof` convert the 32 bit signed (`ltof`) or unsigned (`ultof`) integer in `dx:ax` to a floating point value, leaving the value in the floating point accumulator. These routines always succeed.

`ftoi` converts the value in the floating point accumulator to a signed integer value, leaving the result in `ax`. Conversion is by truncation; this routine keeps the integer portion and throws away the fractional part. If an overflow occurs because the resulting integer portion does not fit into 16 bits, `ftoi` returns the carry flag set. If the conversion occurs without error, `ftoi` return the carry flag clear. `ftou` works in a similar fashion, except it converts the floating point value to an unsigned integer in `ax`; it returns the carry set if the floating point value was negative.

`ftol` and `ftoul` converts the value in the floating point accumulator to a 32 bit integer leaving the result in `dx:ax`. `ftol` works on signed values, `ftoul` works with unsigned values. As with `ftoi` and `ftou`, these routines return the carry flag set if a conversion error occurs.
14.3.3 Floating Point Arithmetic

Floating point arithmetic is handled by the \texttt{fpadd}, \texttt{fpsub}, \texttt{fpcmp}, \texttt{fpmul}, and \texttt{fpdiv} routines. \texttt{fpadd} adds the value in the floating point accumulator to the floating point accumulator. \texttt{fpsub} subtracts the value in the floating point operand from the floating point accumulator. \texttt{fpmul} multiplies the value in the floating accumulator by the floating point operand. \texttt{fpdiv} divides the value in the floating point accumulator by the value in the floating point operand register. \texttt{fpcmp} compares the value in the floating point accumulator against the floating point operand.

The UCR Standard Library arithmetic routines do very little error checking. For example, if arithmetic overflow occurs during addition, subtraction, multiplication, or division, the Standard Library simply sets the result to the largest legal value and returns. This is one of the major deviations from the IEEE floating point standard. Likewise, when underflow occurs the routines simply set the result to zero and return. If you divide any value by zero, the Standard Library routines simply set the result to the largest possible value and return. You may need to modify the standard library routines if you need to check for overflow, underflow, or division by zero in your programs.

The floating point comparison routine (\texttt{fpcmp}) compares the floating point accumulator against the floating point operand and returns -1, 0, or 1 in the \texttt{ax} register if the accumulator is less than, equal, or greater than the floating point operand. It also compares \texttt{ax} with zero immediately before returning so it sets the flags so you can use the \texttt{jg}, \texttt{jge}, \texttt{jl}, \texttt{jle}, \texttt{je}, and \texttt{jne} instructions immediately after calling \texttt{fpcmp}. Unlike \texttt{fpadd}, \texttt{fpsub}, \texttt{fpmul}, and \texttt{fpdiv}, \texttt{fpcmp} does not destroy the value in the floating point accumulator or the floating point operand register. Keep in mind the problems associated with comparing floating point numbers!

14.3.4 Float/Text Conversion and \texttt{printf}

The UCR Standard Library provides three routines, \texttt{ftoa}, \texttt{etoa}, and \texttt{atof}, that let you convert floating point numbers to ASCII strings and vice versa; it also provides a special version of \texttt{printf}, \texttt{printff}, that includes the ability to print floating point values as well as other data types.

\texttt{ftoa} converts a floating point number to an ASCII string which is a decimal representation of that floating point number. On entry, the floating point accumulator contains the number you want to convert to a string. The \texttt{es:di} register pair points at a buffer in memory where \texttt{ftoa} will store the string. The \texttt{al} register contains the field width (number of print positions). The \texttt{ah} register contains the number of positions to display to the right of the decimal point. If \texttt{ftoa} cannot display the number using the print format specified by \texttt{al} and \texttt{ah}, it will create a string of “#” characters, \texttt{ah} characters long. \texttt{es:di} must point at a byte array containing at least \texttt{al+1} characters and \texttt{al} should contain at least five. The field width and decimal length values in the \texttt{al} and \texttt{ah} registers are similar to the values appearing after floating point numbers in the Pascal write statement, e.g.,

\begin{verbatim}
write(floatVal:al:ah);
\end{verbatim}

\texttt{etoa} outputs the floating point number in exponential form. As with \texttt{ftoa}, \texttt{es:di} points at the buffer where \texttt{etoa} will store the result. The \texttt{al} register must contain at least eight and is the field width for the number. If \texttt{al} contains less than eight, \texttt{etoa} will output a string of “#” characters. The string that \texttt{es:di} points at must contain at least \texttt{al+1} characters. This conversion routine is similar to Pascal’s \texttt{write} procedure when writing real values with a single field width specification:

\begin{verbatim}
write(realvar:al);
\end{verbatim}

The Standard Library \texttt{printf} routine provides all the facilities of the standard \texttt{printf} routine plus the ability to handle floating point output. The \texttt{printf} routine includes sev-
eral new format specifications to print floating point numbers in decimal form or using scientific notation. The specifications are:

- `%x.yF` Prints a 32 bit floating point number in decimal form.
- `%x.yGF` Prints a 64 bit floating point number in decimal form.
- `%x.yLF` Prints an 80 bit floating point number in decimal form.
- `%zE` Prints a 32 bit floating point number using scientific notation.
- `%zGE` Prints a 64 bit floating point number using scientific notation.
- `%zLE` Prints an 80 bit floating point value using scientific notation.

In the format strings above, `x` and `z` are integer constants that denote the field width of the number to print. The `y` item is also an integer constant that specifies the number of positions to print after the decimal point. The `x.y` values are comparable to the values passed to `ftoa` in `al` and `ah`. The `z` value is comparable to the value `etoa` expects in the `al` register.

Other than the addition of these six new formats, the `printf` routine is identical to the `printf` routine. If you use the `printf` routine in your assembly language programs, you should not use the `printf` routine as well. `Printff` duplicates all the facilities of `printf` and using both would only waste memory.

### 14.4 The 80x87 Floating Point Coprocessors

When the 8086 CPU first appeared in the late 1970’s, semiconductor technology was not to the point where Intel could put floating point instructions directly on the 8086 CPU. Therefore, they devised a scheme whereby they could use a second chip to perform the floating point calculations – the floating point unit (or FPU)\(^6\). They released their original floating point chip, the 8087, in 1980. This particular FPU worked with the 8086, 8088, 80186, and 80188 CPUs. When Intel introduced the 80286 CPU, they released a redesigned 80287 FPU chip to accompany it. Although the 80287 was compatible with the 80386 CPU, Intel designed a better FPU, the 80387, for use in 80386 systems. The 80486 CPU was the first Intel CPU to include an on-chip floating point unit. Shortly after the release of the 80486, Intel introduced the 80486sx CPU that was an 80486 without the built-in FPU. To get floating point capabilities on this chip, you had to add an 80487 chip, although the 80487 was really nothing more than a full-blown 80486 which took over for the “sx” chip in the system. Intel’s Pentium/586 chips provide a high-performance floating point unit directly on the CPU. There is no floating point coprocessor available for the Pentium chip.

Collectively, we will refer to all these chips as the 80x87 FPU. Given the obsolescence of the 8086, 80286, 8087, and 80287 chips, this text will concentrate on the 80387 and later chips. There are some differences between the 80387/80486/Pentium floating point units and the earlier FPUs. If you need to write code that will execute on those earlier machines, you should consult the appropriate Intel documentation for those devices.

### 14.4.1 FPU Registers

The 80x87 FPUs add 13 registers to the 80386 and later processors: eight floating point data registers, a control register, a status register, a tag register, an instruction pointer, and a data pointer. The data registers are similar to the 80x86’s general purpose register set insofar as all floating point calculations take place in these registers. The control register contains bits that let you decide how the 80x87 handles certain degenerate cases like rounding of inaccurate computations, control precision, and so on. The status register is similar to the 80x86’s flags register; it contains the condition code bits and several other floating point flags that describe the state of the 80x87 chip. The tag register contains several groups of bits that determine the state of the value in each of the eight general purpose registers. The instruction and data pointer registers contain certain state information.

---

6. Intel has also referred to this device as the Numeric Data Processor (NDP), Numeric Processor Extension (NPX), and math coprocessor.
about the last floating point instruction executed. We will not consider the last three regis-
ters in this text, see the Intel documentation for more details.

### 14.4.1.1 The FPU Data Registers

The 80x87 FPU uses eight 80 bit data registers organized as a stack. This is a sig-
nificant departure from the organization of the general purpose registers on the 80x86
CPU that comprise a standard general-purpose register set. Intel refers to these registers
as ST(0), ST(1), ..., ST(7). Most assemblers will accept ST as an abbreviation for ST(0).

The biggest difference between the FPU register set and the 80x86 register set is the
stack organization. On the 80x86 CPU, the ax register is always the ax register, no matter
what happens. On the 80x87, however, the register set is an eight element stack of 80 bit
floating point values (see Figure 14.5). ST(0) refers to the item on the top of the stack, ST(1)
refers to the next item on the stack, and so on. Many floating point instructions push and
pop items on the stack; therefore, ST(1) will refer to the previous contents of ST(0) after
you push something onto the stack. It will take some thought and practice to get used to
the fact that the registers are changing under you, but this is an easy problem to overcome.

### 14.4.1.2 The FPU Control Register

When Intel designed the 80x87 (and, essentially, the IEEE floating point standard),
there were no standards in floating point hardware. Different (mainframe and mini) com-
puter manufacturers all had different and incompatible floating point formats. Unfortu-
nately, much application software had been written taking into account the idiosyncrasies
of these different floating point formats. Intel wanted to designed an FPU that could work
with the majority of the software out there (keep in mind, the IBM PC was three to four
years away when Intel began designing the 8087, they couldn’t rely on that “mountain” of
software available for the PC to make their chip popular). Unfortunately, many of the fea-
tures found in these older floating point formats were mutually exclusive. For example, in
some floating point systems rounding would occur when there was insufficient precision;
in others, truncation would occur. Some applications would work with one floating point
system but not with the other. Intel wanted as many applications as possible to work with
as few changes as possible on their 80x87 FPU/Us, so they added a special register, the FPU
control register, that lets the user choose one of several possible operating modes for the
80x87.

The 80x87 control register contains 16 bits organized as shown in Figure 14.6.

Bit 12 of the control register is only present on the 8087 and 80287 chips. It controls
how the 80x87 responds to infinity. The 80387 and later chips always use a form of
infinity known and affine closure because this is the only form supported by the IEEE
Floating Point Arithmetic

754/854 standards. As such, we will ignore any further use of this bit and assume that it is always programmed with a one.

Bits 10 and 11 provide rounding control according to the following values:

<table>
<thead>
<tr>
<th>Bits 10 &amp; 11</th>
<th>Function</th>
</tr>
</thead>
<tbody>
<tr>
<td>00</td>
<td>To nearest or even</td>
</tr>
<tr>
<td>01</td>
<td>Round down</td>
</tr>
<tr>
<td>10</td>
<td>Round up</td>
</tr>
<tr>
<td>11</td>
<td>Truncate</td>
</tr>
</tbody>
</table>

The “00” setting is the default. The 80x87 rounds values above one-half of the least significant bit up. It rounds values below one-half of the least significant bit down. If the value below the least significant bit is exactly one-half the least significant bit, the 80x87 rounds the value towards the value whose least significant bit is zero. For long strings of computations, this provides a reasonable, automatic, way to maintain maximum precision.

The round up and round down options are present for those computations where it is important to keep track of the accuracy during a computation. By setting the rounding control to round down and performing the operation, then repeating the operation with the rounding control set to round up, you can determine the minimum and maximum ranges between which the true result will fall.

The truncate option forces all computations to truncate any excess bits during the computation. You will rarely use this option if accuracy is important to you. However, if you are porting older software to the 80x87, you might use this option to help when porting the software.

Bits eight and nine of the control register control the precision during computation. This capability is provided mainly to allow compatibility with older software as required by the IEEE 754 standard. The precision control bits use the following values:
For modern applications, the precision control bits should always be set to “11” to obtain 64 bits of precision. This will produce the most accurate results during numerical computation.

Bits zero through five are the exception masks. These are similar to the interrupt enable bit in the 80x86’s flags register. If these bits contain a one, the corresponding condition is ignored by the 80x87 FPU. However, if any bit contains zero, and the corresponding condition occurs, then the FPU immediately generates an interrupt so the program can handle the degenerate condition.

Bit zero corresponds to an invalid operation error. This generally occurs as the result of a programming error. Problem which raise the invalid operation exception include pushing more than eight items onto the stack or attempting to pop an item off an empty stack, taking the square root of a negative number, or loading a non-empty register.

Bit one masks the denormalized interrupt which occurs whenever you try to manipulate denormalized values. Denormalized values generally occur when you load arbitrary extended precision values into the FPU or work with very small numbers just beyond the range of the FPU’s capabilities. Normally, you would probably not enable this exception.

Bit two masks the zero divide exception. If this bit contains zero, the FPU will generate an interrupt if you attempt to divide a nonzero value by zero. If you do not enable the zero division exception, the FPU will produce NaN (not a number) whenever you perform a zero division.

Bit three masks the overflow exception. The FPU will raise the overflow exception if a calculation overflows or if you attempt to store a value which is too large to fit into a destination operand (e.g., storing a large extended precision value into a single precision variable).

Bit four, if set, masks the underflow exception. Underflow occurs when the result is too small to fit in the desitnation operand. Like overflow, this exception can occur whenever you store a small extended precision value into a smaller variable (single or double precision) or when the result of a computation is too small for extended precision.

Bit five controls whether the precision exception can occur. A precision exception occurs whenever the FPU produces an imprecise result, generally the result of an internal rounding operation. Although many operations will produce an exact result, many more will not. For example, dividing one by ten will produce an inexact result. Therefore, this bit is usually one since inexact results are very common.

Bits six and thirteen through fifteen in the control register are currently undefined and reserved for future use. Bit seven is the interrupt enable mask, but it is only active on the 8087 FPU; a zero in this bit enables 8087 interrupts and a one disables FPU interrupts.

The 80x87 provides two instructions, FLDCW (load control word) and FSTCW (store control word), that let you load and store the contents of the control register. The single operand to these instructions must be a 16 bit memory location. The FLDCW instruction loads the control register from the specified memory location, FSTCW stores the control register into the specified memory location.

Table 59: Mantissa Precision Control Bits
14.4.1.3 The FPU Status Register

The FPU status register provides the status of the coprocessor at the instant you read it. The FSTSW instruction stores the 16-bit floating point status register into the mod/reg/rm operand. The status register is a 16-bit register, its layout appears in Figure 14.7.

Bits zero through five are the exception flags. These bits are in the same order as the exception masks in the control register. If the corresponding condition exists, then the bit is set. These bits are independent of the exception masks in the control register. The 80x87 sets and clears these bits regardless of the corresponding mask setting.

Bit six (active only on 80386 and later processors) indicates a stack fault. A stack fault occurs whenever there is a stack overflow or underflow. When this bit is set, the C1 condition code bit determines whether there was a stack overflow (C1=1) or stack underflow (C1=0) condition.

Bit seven of the status register is set if any error condition bit is set. It is the logical OR of bits zero through five. A program can test this bit to quickly determine if an error condition exists.

Bits eight, nine, ten, and fourteen are the coprocessor condition code bits. Various instructions set the condition code bits as shown in the following table:

Bits 11-13 of the FPU status register provide the register number of the top of stack. During computations, the 80x87 adds (modulo eight) the logical register numbers supplied by the programmer to these three bits to determine the physical register number at run time.

Bit 15 of the status register is the busy bit. It is set whenever the FPU is busy. Most programs will have little reason to access this bit.

### 14.4.2 FPU Data Types

The 80x87 FPU supports seven different data types: three integer types, a packed decimal type, and three floating point types. Since the 80x86 CPUs already support integer data types, there are few reasons why you would want to use the 80x87 integer types. The packed decimal type provides a 17 digit signed decimal (BCD) integer. However, we are avoiding BCD arithmetic in this text, so we will ignore this data type in the 80x87 FPU. The remaining three data types are the 32 bit, 64 bit, and 80 bit floating point data types we’ve looked at so far. The 80x87 data types appear in Figure 14.8, Figure 14.9, and Figure 14.10.
The 80x87 FPU generally stores values in a \textit{normalized} format. When a floating point number is normalized, the H.O. bit is always one. In the 32 and 64 bit floating point formats, the 80x87 does not actually store this bit, the 80x87 always assumes that it is one. Therefore, 32 and 64 bit floating point numbers are always normalized. In the extended precision 80 bit floating point format, the 80x87 does \textit{not} assume that the H.O. bit of the mantissa is one, the H.O. bit of the number appears as part of the string of bits.

Normalized values provide the greatest precision for a given number of bits. However, there are a large number of non-normalized values which we \textit{can} represent with the 80 bit format. These values are very close to zero and represent the set of values whose mantissa H.O. bit is not zero. The 80x87 FPs support a special form of 80 bit known as \textit{denormalized} values. Denormalized values allow the 80x87 to encode very small values it cannot encode using normalized values, but at a price. Denormalized values offer less bits of precision than normalized values. Therefore, using denormalized values in a computation may introduce some slight inaccuracy into a computation. Of course, this is always better than underflowing the denormalized value to zero (which could make the computation even less accurate), but you must keep in mind that if you work with very small values you may lose some accuracy in your computations. Note that the 80x87 status register contains a bit you can use to detect when the FPU uses a denormalized value in a computation.

\section*{14.4.3 The FPU Instruction Set}

The 80387 (and later) FPU adds over 80 new instructions to the 80x86 instruction set. We can classify these instructions as \textit{data movement instructions}, \textit{conversions}, \textit{arithmetic instructions}, \textit{comparisons}, \textit{constant instructions}, \textit{transcendental instructions}, and \textit{miscellaneous instructions}. The following sections describe each of the instructions in these categories.

\subsection*{14.4.4 FPU Data Movement Instructions}

The data movement instructions transfer data between the internal FPU registers and memory. The instructions in this category are \texttt{fld}, \texttt{fst}, \texttt{fstp}, and \texttt{fxch}. The \texttt{fld} instructions always pushes its operand onto the floating point stack. The \texttt{fstp} instruction always pops the top of stack after storing the top of stack (tos) into its operation. The remaining instructions do not affect the number of items on the stack.

\subsection*{14.4.4.1 The FLD Instruction}

The \texttt{fld} instruction loads a 32 bit, 64 bit, or 80 bit floating point value onto the stack. This instruction converts 32 and 64 bit operand to an 80 bit extended precision value before pushing the value onto the floating point stack.

The \texttt{fld} instruction first decrements the tos pointer (bits 11-13 of the status register) and then stores the 80 bit value in the physical register specified by the new tos pointer. If the source operand of the \texttt{fld} instruction is a floating point data register, \texttt{ST(i)}, then the actual
register the 80x87 uses for the load operation is the register number before decrementing the tos pointer. Therefore, fld st or fld st(0) duplicates the value on the top of the stack.

The fld instruction sets the stack fault bit if stack overflow occurs. It sets the the denormalized exception bit if you load an 80 bit denormalized value. It sets the invalid operation bit if you attempt to load an empty floating point register onto the stop of stack (or perform some other invalid operation).

Examples:

\[
\begin{align*}
\text{fld} & \quad \text{st}(1) \\
\text{fld} & \quad \text{mem}_32 \\
\text{fld} & \quad \text{MyRealVar} \\
\text{fld} & \quad \text{mem}_64[\text{bx}] \\
\end{align*}
\]

### 14.4.4.2 The FST and FSTP Instructions

The fst and fstp instructions copy the value on the top of the floating point register stack to another floating point register or to a 32, 64, or 80 bit memory variable. When copying data to a 32 or 64 bit memory variable, the 80 bit extended precision value on the top of stack is rounded to the smaller format as specified by the rounding control bits in the FPU control register.

The fstp instruction pops the value off the top of stack when moving it to the destination location. It does this by incrementing the top of stack pointer in the status register after accessing the data in st(0). If the destination operand is a floating point register, the FPU stores the value at the specified register number before popping the data off the top of the stack.

Executing an fstp st(0) instruction effectively pops the data off the top of stack with no data transfer. Examples:

\[
\begin{align*}
\text{fst} & \quad \text{mem}_32 \\
\text{fstp} & \quad \text{mem}_64 \\
\text{fstp} & \quad \text{mem}_64[\text{ebx}*8] \\
\text{fst} & \quad \text{mem}_80 \\
\text{fst} & \quad \text{st}(2) \\
\text{fstp} & \quad \text{st}(1) \\
\end{align*}
\]

The last example above effectively pops st(1) while leaving st(0) on the top of the stack.

The fst and fstp instructions will set the stack exception bit if a stack underflow occurs (attempting to store a value from an empty register stack). They will set the precision bit if there is a loss of precision during the store operation (this will occur, for example, when storing an 80 bit extended precision value into a 32 or 64 bit memory variable and there are some bits lost during conversion). They will set the underflow exception bit when storing an 80 bit value value into a 32 or 64 bit memory variable, but the value is too small to fit into the destination operand. Likewise, these instructions will set the overflow exception bit if the value on the top of stack is too big to fit into a 32 or 64 bit memory variable. The fst and fstp instructions set the denormalized flag when you try to store a denormalized value into an 80 bit register or variable\(^7\). They set the invalid operation flag if an invalid operation (such as storing into an empty register) occurs. Finally, these instructions set the C\(_1\) condition bit if rounding occurs during the store operation (this only occurs when storing into a 32 or 64 bit memory variable and you have to round the mantissa to fit into the destination).

### 14.4.4.3 The FXCH Instruction

The fxch instruction exchanges the value on the top of stack with one of the other FPU registers. This instruction takes two forms: one with a single FPU register as an operand,

\[
\begin{align*}
\text{fxch} & \quad \text{st}(1) \\
\text{fxch} & \quad \text{mem}_32 \\
\text{fxch} & \quad \text{mem}_64 \\
\text{fxch} & \quad \text{mem}_64[\text{bx}*8] \\
\end{align*}
\]

\(^7\) Storing a denormalized value into a 32 or 64 bit memory variable will always set the underflow exception bit.
the second without any operands. The first form exchanges the top of stack with the specified register. The second form of fch swaps the top of stack with st(1).

Many FPU instructions, e.g., fsqrt, operate only on the top of the register stack. If you want to perform such an operation on a value that is not on the top of stack, you can use the fch instruction to swap that register with tos, perform the desired operation, and then use the fch to swap the tos with the original register. The following example takes the square root of st(2):

```
fxch st(2)
fsqrt
fxch st(2)
```

The fch instruction sets the stack exception bit if the stack is empty. It sets the invalid operation bit if you specify an empty register as the operand. This instruction always clears the C1 condition code bit.

### 14.4.5 Conversions

The 80x87 chip performs all arithmetic operations on 80 bit real quantities. In a sense, the fild and fist/fistp instructions are conversion instructions as well as data movement instructions because they automatically convert between the internal 80 bit real format and the 32 and 64 bit memory formats. Nonetheless, we’ll simply classify them as data movement operations, rather than conversions, because they are moving real values to and from memory. The 80x87 FPU provides five routines which convert to or from integer or binary coded decimal (BCD) format when moving data. These instructions are fild, fist, fistp, fbld, and fbstp.

#### 14.4.5.1 The FILD Instruction

The fild (integer load) instruction converts a 16, 32, or 64 bit two’s complement integer to the 80 bit extended precision format and pushes the result onto the stack. This instruction always expects a single operand. This operand must be the address of a word, double word, or quad word integer variable. Although the instruction format for fild uses the familiar mod/rm fields, the operand must be a memory variable, even for 16 and 32 bit integers. You cannot specify one of the 80386’s 16 or 32 bit general purpose registers. If you want to push an 80x86 general purpose register onto the FPU stack, you must first store it into a memory variable and then use fild to push that value of that memory variable.

The fild instruction sets the stack exception bit and C1 (accordingly) if stack overflow occurs while pushing the converted value. Examples:

```
fild mem_16
fild mem_32[ecx*4]
fild mem_64[ebx+ecx*8]
```

#### 14.4.5.2 The FIST and FISTP Instructions

The fist and fistp instructions convert the 80 bit extended precision variable on the top of stack to a 16, 32, or 64 bit integer and store the result away into the memory variable specified by the single operand. These instructions convert the value on tos to an integer according to the rounding setting in the FPU control register (bits 10 and 11). As for the fild instruction, the fist and fistp instructions will not let you specify one of the 80x86’s general purpose 16 or 32 bit registers as the destination operand.

The fist instruction converts the value on the top of stack to an integer and then stores the result; it does not otherwise affect the floating point register stack. The fistp instruction pops the value off the floating point register stack after storing the converted value.
These instructions set the stack exception bit if the floating point register stack is empty (this will also clear C1). They set the precision (imprecise operation) and C1 bits if rounding occurs (that is, if there is any fractional component to the value in st(0)). These instructions set the underflow exception bit if the result is too small (i.e., less than one but greater than zero or less than zero but greater than -1). Examples:

\[
\begin{align*}
\text{fist} & \quad \text{mem}_{16}[bx] \\
\text{fist} & \quad \text{mem}_{64} \\
\text{fistp} & \quad \text{mem}_{32}
\end{align*}
\]

Don’t forget that these instructions use the rounding control settings to determine how they will convert the floating point data to an integer during the store operation. Be default, the rounding control is usually set to “round” mode; yet most programmers expect fist/fistp to truncate the decimal portion during conversion. If you want fist/fistp to truncate floating point values when converting them to an integer, you will need to set the rounding control bits appropriately in the floating point control register.

### 14.4.5.3 The FBLD and FBSTP Instructions

The fbld and fbstp instructions load and store 80 bit BCD values. The fbld instruction converts a BCD value to its 80 bit extended precision equivalent and pushes the result onto the stack. The fbstp instruction pops the extended precision real value on tos, converts it to an 80 bit BCD value (rounding according to the bits in the floating point control register), and stores the converted result at the address specified by the destination memory operand. Note that there is no fbst instruction which stores the value on tos without popping it.

The fbld instruction sets the stack exception bit and C1 if stack overflow occurs. It sets the invalid operation bit if you attempt to load an invalid BCD value. The fbstp instruction sets the stack exception bit and clears C1 if stack underflow occurs (the stack is empty). It sets the underflow flag under the same conditions as fist and fistp. Examples:

\[
\begin{align*}
; & \text{Assuming fewer than eight items on the stack, the following} \\
; & \text{code sequence is equivalent to an fbst instruction:} \\
fld & \text{st}(0) \quad \text{;Duplicate value on TOS.} \\
fbstp & \text{mem}_{80}
\end{align*}
\]

\[
\begin{align*}
; & \text{The following example easily converts an 80 bit BCD value to} \\
; & \text{a 64 bit integer:} \\
fbld & \text{bcd}_{80} \quad \text{;Get BCD value to convert.} \\
fist & \text{mem}_{64} \quad \text{;Store as an integer.}
\end{align*}
\]

### 14.4.6 Arithmetic Instructions

The arithmetic instructions make up a small, but important, subset of the 80x87’s instruction set. These instructions fall into two general categories – those which operate on real values and those which operate on a real and an integer value.

#### 14.4.6.1 The FADD and FADDP Instructions

These two instructions take the following forms:

\[
\begin{align*}
fadd \\
faddd \\
fadd \text{ st}(i), \text{ st}(0) \\
fadd \text{ st}(0), \text{ st}(i) \\
faddd \text{ st}(i), \text{ st}(0) \\
fadd \text{ mem}
\end{align*}
\]
The first two forms are equivalent. They pop the two values on the top of stack, add them, and push their sum back onto the stack.

The next two forms of the \texttt{fadd} instruction, those with two FPU register operands, behave like the 80x86's \texttt{add} instruction. They add the value in the second register operand to the value in the first register operand. Note that one of the register operands must be \texttt{st(0)}\textsuperscript{8}.

The \texttt{faddp} instruction with two operands adds \texttt{st(0)} (which must always be the second operand) to the destination (first) operand and then pops \texttt{st(0)}. The destination operand must be one of the other FPU registers.

The last form above, \texttt{fadd} with a memory operand, adds a 32 or 64 bit floating point variable to the value in \texttt{st(0)}. This instruction will convert the 32 or 64 bit operands to an 80 bit extended precision value before performing the addition. Note that this instruction does not allow an 80 bit memory operand.

These instructions can raise the stack, precision, underflow, overflow, denormalized, and illegal operation exceptions, as appropriate. If a stack fault exception occurs, \texttt{C1} denotes stack overflow or underflow.

\textbf{14.4.6.2 The FSUB, FSUBP, FSUBR, and FSUBRP Instructions}

These four instructions take the following forms:

\begin{verbatim}
    fsub
    fsuob
    fsuob
    fsuobp

    fsub  st(i), st(0)
    fsub  st(0), st(i)
    fsuob st(i), st(0)
    fsuob mem
    fsuob  st(i), st(0)
    fsuob mem
\end{verbatim}

With no operands, the \texttt{fsub} and \texttt{fsuob} instructions operate identically. They pop \texttt{st(0)} and \texttt{st(1)} from the register stack, compute \texttt{st(0)-st(1)}, and push the difference back onto the stack. The \texttt{fsuob} and \texttt{fsuobp} instructions (reverse subtraction) operate in an almost identical fashion except they compute \texttt{st(1)-st(0)} and push that difference.

With two register operands (\texttt{destination, source}) the \texttt{fsub} instruction computes \texttt{destination := destination - source}. One of the two registers must be \texttt{st(0)}. With two registers as operands, the \texttt{fsuob} also computes \texttt{destination := destination - source} and then it pops \texttt{st(0)} off the stack after computing the difference. For the \texttt{fsuobp} instruction, the source operand must be \texttt{st(0)}.

With two register operands, the \texttt{fsuob} and \texttt{fsuobp} instruction work in a similar fashion to \texttt{fsub} and \texttt{fsubp}, except they compute \texttt{destination := source - destination}.

The \texttt{fsub mem} and \texttt{fsuob mem} instructions accept a 32 or 64 bit memory operand. They convert the memory operand to an 80 bit extended precision value and subtract this from \texttt{st(0)} (\texttt{fsub}) or subtract \texttt{st(0)} from this value (\texttt{fsuob}) and store the result back into \texttt{st(0)}.

These instructions can raise the stack, precision, underflow, overflow, denormalized, and illegal operation exceptions, as appropriate. If a stack fault exception occurs, \texttt{C1} denotes stack overflow or underflow.

\textsuperscript{8} Because you will use \texttt{st(0)} quite a bit when programming the 80x87, MASM allows you to use the abbreviation \texttt{st} for \texttt{st(0)}. However, this text will explicitly state \texttt{st(0)} so there will be no confusion.
14.4.6.3 The FMUL and FMULP Instructions

The `fmul` and `fmulp` instructions multiply two floating point values. These instructions allow the following forms:

- `fmul st(0), st(i)`
- `fmul st(i), st(0)`
- `fmul mem`
- `fmulp st(i), st(0)`

With no operands, `fmul` and `fmulp` both do the same thing – they pop `st(0)` and `st(1)`, multiply these values, and push their product back onto the stack. The `fmul` instructions with two register operands compute `destination := destination * source`. One of the registers (source or destination) must be `st(0)`.

The `fmulp st(i), st(0)` instruction computes `st(i) := st(i) * st(0)` and then pops `st(0)`. This instruction uses the value for `i` before popping `st(0)`. The `fmul mem` instruction requires a 32 or 64 bit memory operand. It converts the specified memory variable to an 80 bit extended precision value and the multiplies `st(0)` by this value.

These instructions can raise the stack, precision, underflow, overflow, denormalized, and illegal operation exceptions, as appropriate. If rounding occurs during the computation, these instructions set the `C_1` condition code bit. If a stack fault exception occurs, `C_1` denotes stack overflow or underflow.

14.4.6.4 The FDIV, FDIVP, FDIVR, and FDIVRP Instructions

These four instructions allow the following forms:

- `fdiv st(0), st(i)`
- `fdiv st(i), st(0)`
- `fdivp st(i), st(0)`
- `fdivr st(0), st(i)`
- `fdivr st(i), st(0)`
- `fdivrp st(i), st(0)`
- `fdiv mem`
- `fdivr mem`

With zero operands, the `fdiv` and `fdivp` instructions pop `st(0)` and `st(1)`, compute `st(0)/st(1)`, and push the result back onto the stack. The `fdiv` and `fdivr` instructions also pop `st(0)` and `st(1)` but compute `st(1)/st(0)` before pushing the quotient onto the stack.

With two register operands, these instructions compute the following quotients:

- `fdiv st(0), st(i)` ; `st(0) := st(0)/st(i)`
- `fdiv st(i), st(0)` ; `st(i) := st(i)/st(0)`
- `fdivp st(i), st(0)` ; `st(i) := st(i)/st(0)`
- `fdivr st(0), st(i)` ; `st(0) := st(0)/st(i)`
- `fdivr st(i), st(0)` ; `st(i) := st(i)/st(0)`
- `fdivr st(i), st(0)` ; `st(i) := st(i)/st(0)`
- `fdivr st(i), st(0)` ; `st(i) := st(i)/st(0)`

The `fdivp` and `fdivrp` instructions also pop `st(0)` after performing the division operation. The value for `i` in this two instructions is computed before popping `st(0)`.

These instructions can raise the stack, precision, underflow, overflow, denormalized, zero divide, and illegal operation exceptions, as appropriate. If rounding occurs during the computation, these instructions set the `C_1` condition code bit. If a stack fault exception occurs, `C_1` denotes stack overflow or underflow.
14.4.6.5 The FSQRT Instruction

The fsqrt routine does not allow any operands. It computes the square root of the value on tos and replaces st(0) with this result. The value on tos must be zero or positive, otherwise fsqrt will generate an invalid operation exception.

This instruction can raise the stack, precision, denormalized, and invalid operation exceptions, as appropriate. If rounding occurs during the computation, fsqrt sets the C1 condition code bit. If a stack fault exception occurs, C1 denotes stack overflow or underflow.

Example:

```plaintext
; Compute Z := sqrt(x**2 + y**2);
fld x ; Load X.
fld st(0) ; Duplicate X on TOS.
fmul ; Compute X**2.
fld y ; Load Y.
fld st(0) ; Duplicate Y on TOS.
fmul ; Compute Y**2.
fadd ; Compute X**2 + Y**2.
fsqrt ; Compute sqrt(X**2 + Y**2).
fst Z ; Store away result in Z.
```

14.4.6.6 The FSCALE Instruction

The fscale instruction pops two values off the stack. It multiplies st(0) by 2**st(1) and pushes the result back onto the stack. If the value in st(1) is not an integer, fscale truncates it towards zero before performing the operation.

This instruction raises the stack exception if there are not two items currently on the stack (this will also clear C1 since stack underflow occurs). It raises the precision exception if there is a loss of precision due to this operation (this occurs when st(1) contains a large, negative, value). Likewise, this instruction sets the underflow or overflow exception bits if you multiply st(0) by a very large positive or negative power of two. If the result of the multiplication is very small, fscale could set the denormalized bit. Also, this instruction could set the invalid operation bit if you attempt to fscale illegal values. Fscale sets C1 if rounding occurs in an otherwise correct computation. Example:

```plaintext
fild Sixteen ; Push sixteen onto the stack.
fld x ; Compute x * (2**16).
fscale .
Sixteen word 16
```

14.4.6.7 The FPREM and FPREM1 Instructions

The fprem and fprem1 instructions compute a partial remainder. Intel designed the fprem instruction before the IEEE finalized their floating point standard. In the final draft of the IEEE floating point standard, the definition of fprem was a little different than Intel’s original design. Unfortunately, Intel needed to maintain compatibility with the existing software that used the fprem instruction, so they designed a new version to handle the IEEE partial remainder operation, fprem1. You should always use fprem1 in new software you write, therefore we will only discuss fprem1 here, although you use fprem in an identical fashion.

Fprem1 computes the partial remainder of st(0)/st(1). If the difference between the exponents of st(0) and st(1) is less than 64, fprem1 can compute the exact remainder in one
operation. Otherwise you will have to execute the \texttt{fprem1} two or more times to get the correct remainder value. The \texttt{C2} condition code bit determines when the computation is complete. Note that \texttt{fprem1} does \textit{not} pop the two operands off the stack; it leaves the partial remainder in \texttt{st(0)} and the original divisor in \texttt{st(1)} in case you need to compute another partial product to complete the result.

The \texttt{fprem1} instruction sets the stack exception flag if there aren’t two values on the top of stack. It sets the underflow and denormal exception bits if the result is too small. It sets the invalid operation bit if the values on tos are inappropriate for this operation. It sets the \texttt{C2} condition code bit if the partial remainder operation is not complete. Finally, it loads \texttt{C3}, \texttt{C1}, and \texttt{C0} with bits zero, one, and two of the quotient, respectively.

Example:

\begin{verbatim}
; Compute \( Z := X \mod Y \)
fld y
fld x
PartialLp: fprem1
fistp Z ;Store remainder away.

;Get condition bits in AX.

;See if \texttt{C2} is set.

;Repeat if not done yet.

;Pop old y value.
\end{verbatim}

14.4.6.8 The \texttt{FRNDINT} Instruction

The \texttt{frndint} instruction rounds the value on tos to the nearest integer using the rounding algorithm specified in the control register.

This instruction sets the stack exception flag if there is no value on the tos (it will also clear \texttt{C1} in this case). It sets the precision and denormal exception bits if there was a loss of precision. It sets the invalid operation flag if the value on the tos is not a valid number.

14.4.6.9 The \texttt{FXTRACT} Instruction

The \texttt{fxtract} instruction is the complement to the \texttt{fscale} instruction. It pops the value off the top of the stack and pushes a value which is the integer equivalent of the exponent (in 80 bit real form), and then pushes the mantissa with an exponent of zero (3fffh in biased form).

This instruction raises the stack exception if there is a stack underflow when popping the original value or a stack overflow when pushing the two results (\texttt{C1} determines whether stack overflow or underflow occurs). If the original top of stack was zero, \texttt{fxtract} sets the zero division exception flag. The denormalized flag is set if the result warrants it; and the invalid operation flag is set if there are illegal input values when you execute \texttt{fxtract}.

Example:

\begin{verbatim}
; The following example extracts the binary exponent of \( X \) and
; stores this into the 16 bit integer variable \( Xponent \).
fld x
fxtract
fistp Xponent
\end{verbatim}

14.4.6.10 The \texttt{FABS} Instruction

\texttt{fabs} computes the absolute value of \texttt{st(0)} by clearing the sign bit of \texttt{st(0)}. It sets the stack exception bit and invalid operation bits if the stack is empty.
Example:

; Compute X := sqrt(abs(x));

fld x
fabs
fsqrt
fstp x

14.4.6.11 The FCHS Instruction

Fchs changes the sign of st(0)’s value by inverting its sign bit. It sets the stack exception bit and invalid operation bits if the stack is empty. Example:

; Compute X := -X if X is positive, X := X if X is negative.

fld x
fabs
fchs
fstp x

14.4.7 Comparison Instructions

The 80x87 provides several instructions for comparing real values. The fcom, fcomp, fcompp, fucom, fucomp, and fucompp instructions compare the two values on the top of stack and set the condition codes appropriately. The fst instruction compares the value on the top of stack with zero. The fxam instruction checks the value on tos and reports sign, normalization, and tag information.

Generally, most programs test the condition code bits immediately after a comparison. Unfortunately, there are no conditional jump instructions that branch based on the FPU condition codes. Instead, you can use the fstsw instruction to copy the floating point status register (see “The FPU Status Register” on page 785) into the ax register; then you can use the sahf instruction to copy the ah register into the 80x86’s condition code bits. After doing this, you can can use the conditional jump instructions to test some condition. This technique copies C0 into the carry flag, C2 into the parity flag, and C3 into the zero flag. The sahf instruction does not copy C1 into any of the 80x86’s flag bits.

Since the sahf instruction does not copy any 80x87 processor status bits into the sign or overflow flags, you cannot use the jg, jl, jge, or jle instructions. Instead, use the ja, jae, jb, jbe, je, and jz instructions when testing the results of a floating point comparison. Yes, these conditional jumps normally test unsigned values and floating point numbers are signed values. However, use the unsigned conditional branches anyway; the fstsw and sahf instructions set the 80x86 flags register to use the unsigned jumps.

14.4.7.1 The FCOM, FCOMP, and FCOMPP Instructions

The fcom, fcomp, and fcompp instructions compare st(0) to the specified operand and set the corresponding 80x87 condition code bits based on the result of the comparison. The legal forms for these instructions are

fcom
fcomp
fcompp
fcom st(i)
fcomp st(i)
fcom mem
fcomp mem
With no operands, fcom, fcomp, and fcompp compare st(0) against st(1) and set the processor flags accordingly. In addition, fcomp pops st(0) off the stack and fcompp pops both st(0) and st(1) off the stack.

With a single register operand, fcom and fcomp compare st(0) against the specified register. Fcomp also pops st(0) after the comparison.

With a 32 or 64 bit memory operand, the fcom and fcomp instructions convert the memory variable to an 80 bit extended precision value and then compare st(0) against this value, setting the condition code bits accordingly. Fcomp also pops st(0) after the comparison.

These instructions set C2 (which winds up in the parity flag) if the two operands are not comparable (e.g., NaN). If it is possible for an illegal floating point value to wind up in a comparison, you should check the parity flag for an error before checking the desired condition.

These instructions set the stack fault bit if there aren’t two items on the top of the register stack. They set the denormalized exception bit if either or both operands are denormalized. They set the invalid operation flag if either or both operands are quite NaNs. These instructions always clear the C1 condition code.

### 14.4.7.2 The FUCOM, FUCOMP, and FUCOMPP Instructions

These instructions are similar to the fcom, fcomp, and fcompp instructions, although they only allow the following forms:

```
fucom
fucomp
fucompp
fucom  st(i)
fucomp st(i)
```

The difference between fcom/fcomp/fcompp and fucom/fucomp/fucompp is relatively minor. The fcom/fcomp/fcompp instructions set the invalid operation exception bit if you compare two NaNs. The fucom/fucomp/fucompp instructions do not. In all other cases, these two sets of instructions behave identically.

### 14.4.7.3 The FTST Instruction

The ftst instruction compares the value in st(0) against 0.0. It behaves just like the fcom instruction would if st(1) contained 0.0. Note that this instruction does not differentiate -0.0 from +0.0. If the value in st(0) is either of these values, ftst will set C3 to denote equality. If you need to differentiate -0.0 from +0.0, use the fxam instruction. Note that this instruction does not pop st(0) off the stack.

### 14.4.7.4 The FXAM Instruction

The fxam instruction examines the value in st(0) and reports the results in the condition code bits (see “The FPU Status Register” on page 785 for details on how fxam sets these bits). This instruction does not pop st(0) off the stack.

### 14.4.8 Constant Instructions

The 80x87 FPU provides several instructions that let you load commonly used constants onto the FPU’s register stack. These instructions set the stack fault, invalid opera-
14.4.9 Transcendental Instructions

The 80387 and later FPUs provide eight transcendental (log and trigonometric) instructions to compute a partial tangent, partial arctangent, $2^{x-1}$, $y \cdot \log_2(x)$, and $y \cdot \log_2(x+1)$. Using various algebraic identities, it is easy to compute most of the other common transcendental functions using these instructions.

14.4.9.1 The F2XM1 Instruction

F2xm1 computes $2^{st(0)-1}$. The value in st(0) must be in the range $-1.0 \leq st(0) \leq +1.0$. If st(0) is out of range, f2xm1 generates an undefined result but raises no exceptions. The computed value replaces the value in st(0). Example:

; Compute $10^x$ using the identity: $10^x = 2^{x\cdot \log_2(10)}$ (lg = log 2).

```assemble
fld x
fldl2t
fmul
f2xm1
fld1
fadd
```

Note that f2xm1 computes $2^{x-1}$, which is why the code above adds 1.0 to the result at the end of the computation.

14.4.9.2 The FSIN, FCOS, and FSINCOS Instructions

These instructions pop the value off the top of the register stack and compute the sine, cosine, or both, and push the result(s) back onto the stack. The fsincos pushes the sine followed by the cosine of the original operand, hence it leaves $\cos(st(0))$ in st(0) and $\sin(st(0))$ in st(1).

These instructions assume st(0) specifies an angle in radians and this angle must be in the range $-2^{63} < st(0) < +2^{63}$. If the original operand is out of range, these instructions set the C2 flag and leave st(0) unchanged. You can use the fprem1 instruction, with a divisor of $2\pi$, to reduce the operand to a reasonable range.

These instructions set the stack fault/C1, precision, underflow, denormalized, and invalid operation flags according to the result of the computation.

14.4.9.3 The FPTAN Instruction

Fptan computes the tangent of st(0) and pushes this value and then it pushes 1.0 onto the stack. Like the fsin and fcos instructions, the value of st(0) is assumed to be in radians and must be in the range $-2^{63} < st(0) < +2^{63}$. If the value is outside this range, fptan sets C2 to indicate that the conversion did not take place. As with the fsin, fcos, and fsincos instructions, you can use the fprem1 instruction to reduce this operand to a reasonable range using a divisor of $2\pi$. 

```
fld 
x
fldl2t
fmul
f2xm1
fld1
fadd
```
14.4.9.4 The FPATAN Instruction

This instruction expects two values on the top of stack. It pops them and computes the following:

\[ \text{st}(0) = \tan^{-1}\left( \frac{\text{st}(1)}{\text{st}(0)} \right) \]

The resulting value is the arctangent of the ratio on the stack expressed in radians. If you have a value you wish to compute the tangent of, use \text{fld1} to create the appropriate ratio and then execute the \text{fpatan} instruction.

This instruction affects the stack fault/\(C_1\), precision, underflow, denormal, and invalid operation bits if an problem occurs during the computation. It sets the \(C_1\) condition code bit if it has to round the result.

14.4.9.5 The FYL2X and FYL2XP1 Instructions

The \text{fyl2x} and \text{fyl2xp1} instructions compute \( \text{st}(1) \times \log_2(\text{st}(0)) \) and \( \text{st}(1) \times \log_2(\text{st}(0)+1) \), respectively. \( \text{Fyl2x} \) requires that \( \text{st}(0) \) be greater than zero, \( \text{fyl2xp1} \) requires \( \text{st}(0) \) to be in the range:

\[ -1 - \left( \frac{\sqrt{2}}{2} \right) < \text{st}(0) < \left( 1 - \frac{\sqrt{2}}{2} \right) \]

\( \text{Fyl2x} \) is useful for computing logs to bases other than two; \( \text{fyl2xp1} \) is useful for computing compound interest, maintaining the maximum precision during computation.

\( \text{Fyl2x} \) can affect all the exception flags. \( C_1 \) denotes rounding if there is not other error, stack overflow/underflow if the stack fault bit is set.

The \( \text{fyl2xp1} \) instruction does not affect the overflow or zero divide exception flags. These exceptions occur when \( \text{st}(0) \) is very small or zero. Since \( \text{fyl2xp1} \) adds one to \( \text{st}(0) \) before computing the function, this condition never holds. \( \text{Fyl2xp1} \) affects the other flags in a manner identical to \( \text{fyl2x} \).

14.4.10 Miscellaneous instructions

The 80x87 FPU includes several additional instructions which control the FPU, synchronize operations, and let you test or set various status bits. These instructions include \text{finit/fninit}, \text{fdisi/fndisi}, \text{feni/fneni}, \text{fldow}, \text{fstcw/fnstcw}, \text{fclex/fnclex}, \text{fsave/fnsave}, \text{frstor}, \text{frstpm}, \text{fstsw/fnstsw}, \text{fstenv/fnstenv}, \text{fidenv}, \text{fincstp}, \text{fdecstp}, \text{fwait}, \text{fnop}, and \text{ffree}. The \text{fdisi/fndisi}, \text{feni/fneni}, and \text{frstpm} are active only on FPUs earlier than the 80387, so we will not consider them here.

Many of these instructions have two forms. The first form is \text{Fxxxx} and the second form is \text{FNxxxx}. The version without the “N” emits an \text{fwait} instruction prior to opcode (which is standard for most coprocessor instructions). The version with the “N” does not emit the \text{fwait} opcode (“N” stands for no wait).

14.4.10.1 The FINIT and FNINIT Instructions

The \text{finit} instruction initializes the FPU for proper operation. Your applications should execute this instruction before executing any other FPU instructions. This instruction ini-
itializes the control register to 37Fh (see “The FPU Control Register” on page 782), the status register to zero (see “The FPU Status Register” on page 785) and the tag word to 0FFFFh. The other registers are unaffected.

### 14.4.10.2 The FWAIT Instruction

The `fwait` instruction pauses the system until any currently executing FPU instruction completes. This is required because the FPU on the 80486sx and earlier CPU/FPU combinations can execute instructions in parallel with the CPU. Therefore, any FPU instruction which reads or writes memory could suffer from a data hazard if the main CPU accesses that same memory location before the FPU reads or writes that location. The `fwait` instruction lets you synchronize the operation of the FPU by waiting until the completion of the current FPU instruction. This resolves the data hazard by, effectively, inserting an explicit “stall” into the execution stream.

### 14.4.10.3 The FLDCW and FSTCW Instructions

The `fldcw` and `fstcw` instructions require a single 16 bit memory operand:

```
fldcw mem_16
fstcw mem_16
```

These two instructions load the control register (see “The FPU Control Register” on page 782) from a memory location (`fldcw`) or store the control word to a 16 bit memory location (`fstcw`).

When using the `fldcw` instruction to turn on one of the exceptions, if the corresponding exception flag is set when you enable that exception, the FPU will generate an immediate interrupt before the CPU executes the next instruction. Therefore, you should use the `fclex` instruction to clear any pending interrupts before changing the FPU exception enable bits.

### 14.4.10.4 The FCLEX and FNCLEX Instructions

The `fclex` and `fnclex` instructions clear all exception bits the stack fault bit, and the busy flag in the FPU status register (see “The FPU Status Register” on page 785).

### 14.4.10.5 The FLDENV, FSTENV, and FNSTENV Instructions

```
fstenv mem_14b
fnstenv mem_14b
fldenv mem_14b
```

The `fstenv/fnstenv` instructions store a 14-byte FPU environment record to the memory operand specified. When operating in real mode (the only mode this text considers), the environment record takes the form appearing in Figure 14.11.

You must execute the `fstenv` and `fnstenv` instructions with the CPU interrupts disabled. Furthermore, you should always ensure that the FPU is not busy before executing this instruction. This is easily accomplished by using the following code:

```
pushf ;Preserve I flag.
c1i ;Disable interrupts.
fstenv mem_14b ;Implicit wait for not busy.
fwait ;Wait for operation to finish.
popf ;Restore I flag.
```

The `fldenv` instruction loads the FPU environment from the specified memory operand. Note that this instruction lets you load the the status word. There is no explicit instruction like `fldcw` to accomplish this.
14.4.10.6 The FSAVE, FNSAVE, and FRSTOR Instructions

These instructions save and restore the state of the FPU. This includes saving all the internal control, status, and data registers. The destination location for fsave/fnsave (source location for frstor) must be 94 bytes long. The first 14 bytes correspond to the environment record the fldenv and fstenv instructions use; the remaining 80 bytes hold the data from the FPU register stack written out as st(0) through st(7). Frstor reloads the environment record and floating point registers from the specified memory operand.

The fsave/fnsave and frstor instructions are mainly intended for task switching. You can also use fsave/fnsave and frstor as a “push all” and “pop all” sequence to preserve the state of the FPU.

Like the fstenv and fldenv instructions, interrupts should be disabled while saving or restoring the FPU state. Otherwise another interrupt service routine could manipulate the FPU registers and invalidate the operation of the fsave/fnsave or frstore operation. The following code properly protects the environment data while saving and restore the FPU status:

; Preserve the FPU state, assume di points at the environment record in memory.

pushf
cli
fsave [si]
fwait
popf
.
.
pushf
cli
frstor [si]
fwait
popf
14.4.10.7 The FSTSW and FNSTSW Instructions

```
fstsw   ax
fnstsw  ax
fstsw   mem_16
fnstsw  mem_16
```

These instructions store the FPU status register (see “The FPU Status Register” on page 785) into a 16 bit memory location or the ax register. These instructions are unusual in the sense that they can copy an FPU value into one of the 80x86 general purpose registers. Of course, the whole purpose behind allowing the transfer of the status register into ax is to allow the CPU to easily test the condition code register with the sahf instruction.

14.4.10.8 The FINCSTP and FDECSTP Instructions

The fincstp and fdecstp instructions do not take any operands. They simply increment and decrement the stack pointer bits (mod 8) in the FPU status register. These two instructions clear the C1 flag, but do not otherwise affect the condition code bits in the FPU status register.

14.4.10.9 The FNOP Instruction

The fnop instruction is simply an alias for fst st, st(0). It performs no other operation on the FPU.

14.4.10.10 The FFREE Instruction

```
ffree   st(i)
```

This instruction modifies the tag bits for register i in the tags register to mark the specified register as empty. The value is unaffected by this instruction, but the FPU will no longer be able to access that data (without resetting the appropriate tag bits).

14.4.11 Integer Operations

The 80x87 FPUs provide special instructions that combine integer to extended precision conversion along with various arithmetic and comparison operations. These instructions are the following:

```
fiadd   int
fisub   int
fisubr  int
fimul   int
fidiv   int
fidivr  int
ficom   int
ficomp  int
```

These instructions convert their 16 or 32 bit integer operands to an 80 bit extended precision floating point value and then use this value as the source operand for the specified operation. These instructions use st(0) as the destination operand.
14.5 Sample Program: Additional Trigonometric Functions

This section provides various examples of 80x87 FPU programming. This group of routines provides several trigonometric, inverse trigonometric, logarithmic, and exponential functions using various algebraic identities. All these functions assume that the input values are on the stack are are within valid ranges for the given functions. The trigonometric routines expect angles expressed in radians and the inverse trig routines produce angles measured in radians.

This program (transcnd.asm) appears on the companion CD-ROM.

14.6 Laboratory Exercises
14.6.1 FPU vs StdLib Accuracy

In this laboratory exercise you will run two programs that perform 20,000,000 floating point additions. These programs do the first 10,000,000 additions using the 80x87 FPU, they do the second 10,000,000 additions using the Standard Library’s floating point routines. This exercise demonstrates the relative accuracy of the two floating point mechanisms.

**For your lab report:** assemble and run the Ex14_1.asm program (it’s on the companion CD-ROM). This program adds together 10,000,000 64-bit floating point values and prints their sum. Describe the results in your lab report. Time these operations and report the time difference in your lab report. Note that the exact sum these operations should produce is 1.00000010000e+0000.

After running Ex14_1.asm, repeat this process for the Ex14_2.asm file. Ex14_2 differs from Ex14_1 insofar as Ex14_2 lets the Standard Library routines operate on 80-bit memory operands (the FPU cannot operate on 80-bit memory operands, so this part remains unchanged). Time the execution of Ex14_2’s two components. Compare these times against the running time of Ex14_1 and explain any differences.

```assembly
; EX14_1.asm
;
; This program runs some tests to determine how well the floating point arithmetic in the Standard Library compares with the floating point arithmetic on the 80x87. It does this performing various operations using both methods and comparing the result.
;
; Of course, you must have an 80x87 FPU (or 80486 or later processor) in order to run this code.

14.7 Programming Projects

14.8 Summary

For many applications integer arithmetic has two insurmountable drawbacks – it is not easy to represent fractional values with integers and integers have a limited dynamic range. Floating point arithmetic provides an approximation to real arithmetic that overcomes these two limitations.

Floating point arithmetic, however, is not without its own problems. Floating point arithmetic suffers from limited precision. As a result, inaccuracies can creep into a calculation. Therefore, floating point arithmetic does not completely follow normal algebraic rules. There are five very important rules to keep in mind when using floating point arithmetic: (1) The order of evaluation can affect the accuracy of the result; (2) Whenever adding and subtracting numbers, the accuracy of the result may be less than the precision provided by the floating point format; (3) When performing a chain of calculations involving addition, subtraction, multiplication, and division, try to perform the multiplication and division operations first; (4) When multiplying and dividing values, try to multiply large and small numbers together first and try to divide numbers with the same relative magnitude first; (5) When comparing two floating point numbers, always keep in mind that errors can creep into the computations, therefore you should check to see if one value is within a certain range of the other. For more information, see

- “The Mathematics of Floating Point Arithmetic” on page 771

Early on Intel recognized the need for a hardware floating point unit. They hired three mathematicians to design highly accurate floating point formats and algorithms for their 80x87 family of FPU’s. These formats, with slight modifications, become the IEEE 754 and IEEE 854 floating point standards. The IEEE standard actually provides for three different formats: a 32 bit standard precision format, a 64 bit double precision format, and an extended precision format. Intel implemented the extended precision format using 80 bits9. The 32 bit format uses a 24 bit mantissa (the H.O. bit is an implied one and is not stored in the 32 bits), an eight bit bias 127 exponent, and a one bit sign. The 64 bit format provides a 53 bit mantissa (again, the H.O. bit is always one and is not stored in the 64 bit value), an 11 bit excess 1023 exponent, and a one bit sign. The 80 bit extended precision format uses a 64 bit exponent, a 15 bit excess 16363 exponent, and a single bit sign. For more information, see

- “IEEE Floating Point Formats” on page 774

---

9. The IEEE standard only requires that the extended precision format contain more bits than the double precision format.
Although 80x87 FPUs and CPUs with built-in FPUs (80486 and Pentium) are becoming very common, it is still possible that you may need to execute code that uses floating point arithmetic on a machine without an FPU. In such cases you will need to supply software routines to execute the floating point arithmetic. Fortunately, the UCR Standard Library provides a set of floating point routines you can call. The Standard Library includes routines to load and store floating point values, convert between integer and floating point formats, add, subtract, multiply, and divide floating point values, convert between ASCII and floating point, and output floating point values. Even if you have an FPU installed, the Standard Library’s conversion and output routines are quite useful. For more information, see

- “The UCR Standard Library Floating Point Routines” on page 777

For fast floating point arithmetic, software doesn’t stand a chance against hardware. The 80x87 FPUs provide fast and convient floating point operations by extended the 80x86’s instruction set to handle floating point arithmetic. In addition to the new instructions, the 80x87 FPUs also provide eight new data registers, a control register, a status register, and several other internal registers. The FPU data registers, unlike the 80x86’s general purpose registers, are organized as a stack. Although it is possible to manipulate the registers as thought they were a standard register file, most FPU applications use the stack mechanism when computing floating point results. The FPU control register lets you initialize the 80x87 FPU in one of several different modes. The control register lets you set the rounding control, the precision available during computation, and choose which exceptions can cause an interrupt. The 80x87 status register reports the current state of the FPU. This register provides bits that determine if the FPU is currently busy, determine if a previous instruction has generated an exception, determine the physical register number of the top of the register stack, and provide the FPU condition codes. For more information on the 80x87 register set, see

- “The 80x87 Floating Point Coprocessors” on page 781
- “FPU Registers” on page 781
- “The FPU Data Registers” on page 782
- “The FPU Control Register” on page 782
- “The FPU Status Register” on page 785

In addition to the IEEE single, double, and extended precision data types, the 80x87 FPUs also support various integer and BCD data types. The FPU will automatically convert to and from these data types when loading and storing such values. For more information on these data type formats, see

- “FPU Data Types” on page 788

The 80x87 FPUs provide a wide range of floating point operations by augmenting the 80x86’s instruction set. We can classify the FPU instructions into eight categories: data movement instructions, conversions, arithmetic instructions, comparison instructions, constant instructions, transcendental instructions, miscellaneous instructions, and integer instructions. For more information on these instruction types, see

- “The FPU Instruction Set” on page 789
- “FPU Data Movement Instructions” on page 789
- “Conversions” on page 791
- “Arithmetic Instructions” on page 792
- “Comparison Instructions” on page 797
- “Constant Instructions” on page 798
- “Transcendental Instructions” on page 799
- “Miscellaneous instructions” on page 800
- “Integer Operations” on page 803

Although the 80387 and later FPUs provide a rich set of transcendental functions, there are many trigonometric, inverse trigonometric, exponential, and logarithmic functions missing from the instruction set. However, the missing functions are easy to synthesize using algebraic identities. This chapter provides source code for many of these routines as an example of FPU programming. For more information, see
• “Sample Program: Additional Trigonometric Functions” on page 804
14.9 Questions

1) Why don’t the normal rules of algebra apply to floating point arithmetic?
2) Give an example of a sequence of operations whose order of evaluation will produce different results with finite precision arithmetic.
3) Explain why limited precision addition and subtraction operations can cause a loss of precision during a calculation.
4) Why should you, if at all possible, perform multiplications and divisions first in a calculation involving multiplication or division as well as addition or subtraction?
5) Explain the difference between a normalized, unnormalized, and denormalized floating point value.
6) Using the UCR Standard Library, convert the following expression to 80x86 assembly code (assume all variables are 64 bit double precision values). Be sure to perform any necessary algebraic manipulations to ensure the maximum accuracy. You can assume all variables fall in the range ±1e-10…±1e+10.
   a) Z := X * X + Y * Y
   b) Z := (X-Y)*Z
   c) Z := X*Y - X/Y
   d) Z := (X+Y)/(X-Y)
   e) Z := (X*X)/(Y*Y)
   f) Z := X*X + Y + 1.0
7) Convert the above statements to 80x87 FPU code.
8) The following problems provide definitions for the hyperbolic trigonometric functions. Encode each of these using the 80x87 FPU instructions and the exp(x) and ln(x) routines provided in this chapter.
   a) sinh x = \frac{e^x - e^{-x}}{2}
   b) cosh x = \frac{e^x + e^{-x}}{2}
   c) tanh x = \frac{\sinh x}{\cosh x}
   d) csch x = \frac{1}{\sinh x}
   e) sech x = \frac{1}{\cosh x}
   f) coth x = \frac{\cosh x}{\sinh x}
   g) asinh x = \ln(x + \sqrt{x^2 + 1})
   h) acosh x = \ln(x + \sqrt{x^2 - 1})
   i) atanh x = \frac{\ln(1 + x)}{2}
   j) acsch x = \ln\left(\frac{x + \sqrt{1 + x^2}}{x}\right)
   k) asech x = \ln\left(\frac{x}{x - \sqrt{1 - x^2}}\right)
   l) atanh x = \frac{\ln\left(\frac{x + 1}{x - 1}\right)}{2}
9) Create a log(x,y) function which computes log_y x. The algebraic identity for this is
   \log_y x = \frac{\log_x x}{\log_x y}
10) Interval arithmetic involves performing a calculation with every result rounded down and then repeating the computation with each result rounded up. At the end of these two computations, you know that the true result must lie between the two computed results. The rounding control bits in the FPU control register let you select round up and round down modes. Repeat question six applying interval arithmetic and compute the two bounds for each of those problems (a-f).
11) The mantissa precision control bits in the FPU control register simply control where the FPU rounds results. Selecting a lower precision does not improve the performance of the FPU. Therefore, any new software you write should set these two bits to ones to get 64 bits of precision when performing calculations. Can you provide one reason why you might want to set the precision to something other than 64 bits?

12) Suppose you have two 64 bit variables, X and Y, that you want to compare to see if they are equal. As you know, you should not compare them directly to see if they are equal, but rather see if they are less than some small value apart. Suppose \( \epsilon \), the error constant, is \( 1e^{-300} \). Provide the code to load ax with zero if \( X = Y \) and load ax with one if \( X \neq Y \).

13) Repeat problem 12, except test for:
   a) \( X \leq Y \)   
   b) \( X < Y \)   
   c) \( X \geq Y \)   
   d) \( X > Y \)   
   e) \( X \neq Y \)

14) What instruction can you use to see if the value in st(0) is denormalized?

15) Assuming no stack underflow or overflow, what is the \( C_I \) condition code bit usually used for?

16) Many texts, when describing the FPU chip, suggest that you can use the FPU to perform integer arithmetic. An argument generally given is that the FPU can support 64 bit integers whereas the CPU can only support 16 or 32 bit integers. What is wrong with this argument? Why would you not want to use the FPU to perform integer arithmetic? Why does the FPU even provide integer instructions?

17) Suppose you have a 64 bit double precision floating point value in memory. Describe how you could take the absolute value of this variable without using the FPU (i.e., by using only 80x86 instructions).

18) Explain how to change the sign of the variable in question 17.

19) Why does the TwoToX function (see “Sample Program: Additional Trigonometric Functions” on page 804) have to compute the result using fscale and fyl2x? Why can’t it use fyl2x along?

20) Explain a possible problem with the following code sequence:

\[
\begin{align*}
stp & \quad \text{mem}_64 \\
xor & \quad \text{byte ptr mem}_64+7, 80h  \\
& \quad ;\text{Tweak sign bit}
\end{align*}
\]
